# ABSTRACT

This paper presents a semantics-based compilation framework for an aspect-oriented programming language based on its operational semantics model. Using partial evaluation, the framework can explain several issues in compilation processes, including how to find places in program text to insert aspect code and how to remove unnecessary run-time checks. It also illustrates optimization of calling-context sensitive pointcuts (cflow), implemented in real compilers.

# **Keywords**

Aspect SandBox, dynamic join point model, partial evaluation, Futamura projection, compile-time weaving, contextsensitive pointcut designators (cflow)

# 1. INTRODUCTION

This work is part of a larger project, the Aspect Sand-Box (ASB), that aims to provide concise models of aspectoriented programming (AOP) for theoretical studies and to provide a tool for prototyping alternative AOP semantics and implementation techniques. To avoid difficulties to develop formal semantics directly from artifacts as complex as AspectJ and Hyper/J, ASB provides a suite of interpreters of simplified languages. Those languages have sufficient features to characterize existing AOP languages. In this paper we report one result from the ASB project—a semanticsbased explanation of the compilation strategy for advice dispatch in AspectJ like languages[6, 7, 11, 12].

The idea is to use partial evaluation to perform as many tests as possible at compile-time, and to insert applicable advice bodies directly into the program. Our semantic framework also explains the optimization used by the AspectJ compiler for context-sensitive pointcuts (cflow and cflowbelow).

Some of the issues our semantic framework clarifies include:

- The mapping between dynamic join points and the points in the program text, or *join point shadows*, where the compiler actually operates.
- What dispatch can be 'compiled-out' and what must be done at runtime.
- The performance impact different kinds of advice and pointcuts can have on a program.
- How the compiler must handle recursive application of advice.

### **1.1 Join Point Models**

Aspect-oriented programming (AOP) is a paradigm to modularize crosscutting concerns[13]. An AOP program is effectively written in multiple modularities—concerns that are local in one are diffuse in another and vice-versa. Thus far, several AOP languages are proposed from practical to experimental levels[3, 11, 12, 16, 17].

The ability of an AOP language to support crosscutting lies in its *join point model* (JPM). A JPM consists of three elements:

- The *join points* are the points of reference that aspect programs can use to refer to the computation of the whole program. *Lexical* join points are locations in the program text (*e.g.*, "the body of a method"). *Dynamic* join points are run-time entities, such as events that take place during execution of the program (*e.g.*, "an invocation of a method").
- A means of identifying join points. (e.g., "the bodies of methods in a particular class," or "all invocations of a particular method")
- A means of specifying semantics at join points. (e.g., "run this code beforehand")

As an example, in AspectJ:

<sup>&</sup>lt;sup>\*</sup>This work is carried out during his visit to University of British Columbia.

- the join points are nodes in the runtime control flow graph of the program, such as when a method is called (and returns), and when a field is read (and the value is returned). (*e.g.*, "a call to method set(int) of class Point"<sup>1</sup>)
- the means of identifying join points is the *pointcut* mechanism, which can pick out join points based on things like the name of the method, the package, the caller, and so forth. (*e.g.*, "call(void Point.set(int))")
- the means of specifying semantics is the *advice* mechanism, which makes it possible to specify additional code that should run at join points. (*e.g.*, "before : call(void Point.set(int))

{ Log.add("set"); }")

In this paper, we will be working with a simplified JPM similar to the one from AspectJ. (See Section 2.1 for details.)

The rest of the paper is organized as follows. Section 2 introduces our AOP language, AJD, and shows its interpreter. Section 3 presents a compilation framework for AJD excluding context-sensitive pointcuts, which are deferred to Section 4. Section 5 relates our study to other formal studies in AOP and other compilation frameworks. Section 6 concludes the paper with future directions.

# 2. AJD: DYNAMIC JOIN POINT MODEL AOP LANGUAGE

This section introduces our small AOP language, AJD, which implements core features of AspectJ's dynamic join point model. The language consists of a simple object-oriented language and its AOP extension. Its operational semantics is given as an interpreter written in Scheme. A formalization of a procedural subset of AJD is presented by Wand and the second and the third authors[20].

# 2.1 Informal Semantics

We first informally present the semantics of AJD. In short, AJD is an AOP language based on a simple object-oriented language with classes, objects, instance variables, and methods. Its AOP features covers essential part of AspectJ (version 1.0).

# 2.1.1 Object Semantics

Figure 1 is an example program. For readability, we use a Java-like syntax in the paper<sup>2</sup>. It defines a Point class with one integer instance variable x, a unary constructor, and three methods set, move and main.

When method main of a Point object is executed, line 7 creates another Point object and runs the constructor defined at line 3. Line 8 invokes method move on the created object. Finally, line 9 reads and displays the value of variable x of the object.

```
class Point {
1
2
       int x:
3
       Point(int ix)
                            { this.set(ix): }
4
       void set(int newx) { this.x = newx; }
\mathbf{5}
       void move(int dx) { this.set(this.x + dx); }
6
       void main() {
7
         Point p = new Point(1);
8
         p.move(5);
9
         write(p.x); newline();
10
       }
     }
11
```

Figure 1: An Example Program. (write and newline are primitive operators.)

 $\begin{array}{ll} p \in \{ \text{pointcuts} \}, & m \in \{ \text{method signatures} \}, \\ n \in \{ \text{constructor signatures} \}, & v \in \{ \text{identifiers with types} \} \end{array}$  $\begin{array}{ll} p & ::= & \texttt{call}(m) \mid \texttt{execution}(m) \mid \texttt{new}(n) \\ & \mid & \texttt{target}(v) \mid \texttt{args}(v, \ldots) \mid p \texttt{kkp} \mid p \mid |p| \mid p \\ & \mid & \texttt{cflow}(p) \mid \texttt{cflowbelow}(p) \end{array}$ 

### Figure 2: Syntax of Pointcuts.

# 2.1.2 Aspect Semantics

To explain the semantics of AOP features in AJD, we first define its JPM.

# 2.1.2.1 Join Point

The *join point* is an action during program execution, including method calls, method execution, object creation, and advice execution. (Note that a method invocation is treated as a call join point at the caller's side and an execution join point at the receiver's side.) The *kind* of the join point is the kind of action (*e.g.*, call and execution).

# 2.1.2.2 Means of Identifying Join Points

The means of identifying join points is the pointcut mechanism. A *pointcut* is a predicate on join points, which is used to specify the join points that a piece of advice applies to. The syntax of pointcuts is shown in Figure 2. Since pointcuts can have parameters, the evaluation of a pointcut with respect to a join point results in either bindings that satisfy the pointcut (meaning true), or false.

The first three pointcuts (call, execution, and new) match join points that have the same kind and signature as the pointcut. The next two pointcuts (target and args) match any join point that has values of specified types. The next three operators (&&, || and !) logically combine or negate pointcuts. The last two pointcuts match join points that have a join point matching their sub-pointcuts in the callstack. These are discussed in Section 4 in more detail. Interpretation of pointcuts is formally presented in other literature[20].

### 2.1.2.3 Means of Specifying Semantics

The means of specifying semantics is the advice mechanism. A piece of *advice* contains a pointcut and a body expression. When a join point is created, and it matches the pointcut of a piece of advice, the body of the advice is executed. There are two types of advice, namely **before** and **after**. A **before** 

<sup>&</sup>lt;sup>1</sup>For simplicity later in the paper, we are using onedimensional points as an example.

 $<sup>^2 \</sup>rm Our$  implementation actually uses an S-expression based syntax.

```
1 before : call(void Point.set(int)) && args(int z) {
2 write("set:"); write(z); newline();
3 }
```

```
Figure 3: Example Advice.
```

```
1
     (define eval
\mathbf{2}
       (lambda (exp env jp)
3
          (cond
4
          ((const-exp? exp) (const-value exp))
5
          ((var-exp? exp) (lookup env (var-name exp)))
6
          ((call-exp? exp)
           (call (call-signature exp)
\overline{7}
8
                  (eval (call-target exp) env jp)
9
                  (eval-rands (call-rands exp) env jp)
10
                  jp))
          ...)))
11
12
     (define call
       (lambda (sig obj args jp)
13
14
         (execute (lookup-method (object-class obj) sig)
15
                   obj args jp)))
16
     (define execute
       (lambda (method this args jp)
17
18
         (let ((class (method-class method))
19
                (params (method-params method)))
            (eval (method-body method)
20
21
                  (new-env (list* 'this '%host params)
22
                            (list* this class args))
23
                  jp))))
```

Figure 4: Expression Interpreter.

advice is executed before the original action is taken place. Similarly, the **after** is executed after the original action is completed.

Figure 3 shows an example of advice that lets the example program to print a message before every call to method set. The keyword **before** specifies the type of the advice. pointcut is written after the colon. The pointcut matches join points that call method set of class Point, and the args sub-pointcut binds variable z to the argument to method set. Line 2 is the body, which prints messages and the value of the argument.

When the program in Figure 1 is executed together with the advice in Figure 3, the advice matches to the call to set twice (in the constructor and in method set), it thus will print "set:1", "set:6" and "6".

#### 2.2 AJD Interpreter

The interpreter of AJD consists of an expression interpreter and several definitions for AOP features including the data structure for a join point, wrappers for creating join points, a weaver, and a pointcut interpreter.

#### 2.2.1 Expression Interpreter

Figure 4 shows the core of the expression interpreter excluding support for AOP features. The main function eval takes an expression, an environment, and a join point as its parameters. The join point is an execution join point at the enclosing method or constructor.

An expression is a parsed abstract syntax tree. There are predicates (*e.g.*, const-exp? and call-exp?) and selectors (*e.g.*, const-value and call-signature) for the syntax

	field	available information
	kind	call, execution, etc.
	name	name of method or class
	target	target of method invocation
	args	arguments to a method
	stack	(explained in Section 4)
Table 1: Fields in Join Points         1       (define call		
2	(lambda (sig obj args jp)	
3	(weave (make-jp 'call sig obj args jp)	
4	(lambda (args jp)	
5	;; body of the original call goes here	
6	)	
7	args	)))

Figure 5: A Wrapper.

trees. An environment binds variables to mutable cells; *i.e.*, an assignment to a variable is implemented as side-effect in Scheme. An object is a Scheme data structure that has a class information and mutable fields for instance variables. Likewise, an assignment to an instance variable is implemented as side-effect.

Each action that creates join points is defined as a separate sub-function, so that we can add AOP support later.

For example, the interpreter evaluates a method call expression in the following manner. First, sub-expressions for the target object and operand values are recursively evaluated (ll.8–9). Next, in function call, a method is looked-up in the class of the target object (l.14). Then, in function execute, an environment that binds the formal parameters to the operand values is created (ll.25–26)<sup>3</sup>. Finally, the body of the method is evaluated with newly created environment (ll.24–27).

#### 2.2.2 Join Point

A join point is a data structure that is created upon an action in the expression interpreter. A piece of advice obtains all information about advised action from join points. In our implementation, a join point is a record of kind, name, target, args, and stack. Table 1 summarizes values in those fields. There are selectors, such as jp-kind, and a constructor, make-jp, for accessing and creating join points.

#### 2.2.3 Wrapper

In order to advice actions performed in the expression interpreter, we wrap the interpreter functions so that they (conceptually) create dynamic join points. Figure 5 shows how call—one of such a function—is wrapped. When a method is to be called, the function first creates a join point that represents the call action (1.3) and applies it to weave, which executes advice applicable to the join point (explained below). The lambda-closure passed to weave (ll.4–6) defines the action of call, which is executed during the weaving process.

Likewise, the other functions including method execution,

 $<sup>^{3}\</sup>mathrm{The}$  pseudo-variable  $\texttt{\host}$  is used for looking-up methods for super classes.

```
1
     (define weave
 \mathbf{2}
       (lambda (jp action args)
 3
          (call-befores/afters *befores* args jp)
 4
          (let ((result (action args jp)))
 \mathbf{5}
            (call-befores/afters *afters* args jp)
 \mathbf{6}
            result)))
      (define call-befores/afters
 7
 8
       (lambda (advs args jp)
9
          (for-each (call-before/after args jp) advs)))
10
      (define call-before/after
11
       (lambda (args jp)
12
          (lambda (adv)
13
            (let ((env (pointcut-match? (advice-pointcut adv)
14
                                           jp)))
15
              (if env
16
                   (execute-before/after adv env jp))))))
17
      (define execute-before/after
18
       (lambda (adv env jp)
19
          (weave (make-jp 'aexecution adv #f #f '() jp)
                 (lambda (args jp)
20
21
                    (eval (advice-body adv) env jp))
22
                  ·())))
```

#### Figure 6: Weaver.

```
1
     (define pointcut-match?
       (lambda (pc jp)
\mathbf{2}
3
          (cond
4
           ((and (call-pointcut? pc) (call-jp? jp)
                 (sig-match? (pointcut-sig pc) (jp-name jp)))
\mathbf{5}
6
            (make-env '() '()))
7
           ((and (args-pointcut? pc)
8
                 (types-match? (jp-args jp)
9
                                 (pointcut-arg-types pc)))
10
            (make-env (pointcut-arg-names pc) (jp-args jp)))
11
           (else #f))))
12
```

#### Figure 7: Pointcut Interpreter.

object creation, and advice execution (defined later) are wrapped.

#### 2.2.4 Weaver

Figure 6 shows the definition of the weaver. Function weave takes a join point (jp), a lambda-closure for continuing the original action (action), and a list of arguments to action (args). It also uses advice definitions in global variables (\*befores\* and \*afters\*). It defines the order of advice execution; it executes befores first, then the original action, followed by afters last.

Function call-befores/afters processes a list of advice. It matches the pointcut of each piece of advice against the current join point (ll.13–14), and executes the body of the advice if they match (ll.15–16). In order to (potentially) advise execution of advice, the function execute-before/after is also wrapped. Line 21 actually executes the advice body in an environment that provides the bindings expressed by the pointcut.

Calling around advice has basically the same structure for the **before** and **after**. It is, however, more complicated due to its interleaved execution for the **proceed** mechanism.

#### 2.2.5 Pointcut interpreter

The pointcut interpreter **pointcut-match**?, shown in Figure 7, matches a pointcut to a join point. Due to space limitations, we only show rules for two types of pointcuts. The first rule (ll.4-6) defines that a call(m) pointcut matches to a call join point that whose name field matches to m. It returns an empty environment that represent 'true' (l.6). An  $args(t \ x, \ldots)$  pointcut (where t and x are a type and a variable, respectively) matches to any join point whose arguments have the same type to  $t, \ldots$  (ll.7-10). It returns an environment that binds variable  $x, \ldots$  in the pointcut to the value of the argument in the join point (l.10). False is returned when matching fails (l.12).

# 3. COMPILING AJD PROGRAMS BY PARTIAL EVALUATION

# 3.1 Outline

Our compilation framework is based on partial evaluation of an interpreter, which is known as the first Futamura projection[9]. Given an interpreter of a language and a program to be interpreted, partially evaluating the interpreter with respect to the subject program generates a compiled program (called a *residual* program). Following this scheme, we can expect that partial evaluation of an AOP interpreter with respect to a subject program and advice definitions would generate a compiled, or statically woven program.

While the AJD interpreter is written as to 'test-and-execute' *all* pieces of advice at each *dynamic* join point, our compilation framework successfully inserts *only applicable* advice to each shadow of join points. This is achieved in the following way:

- 1. Our compilation framework runs partial evaluation with AJD interpreter and each method definition.
- 2. The partial evaluator processes the expression interpreter, which virtually walks over the expressions in the method. All shadows of join points are thus instantiated.
- 3. At each shadow of join points, the partial evaluator further processes the weaver. Using statically given advice definitions, it (conceptually) inserts test-andexecute sequence of all advice.
- 4. For each piece of advice, the partial evaluator reduces the test-and-execute code into a conditional branch whose condition is either constant or dynamic value, and then-clause executes the advice body. Depending on the condition, the entire code or the test code may be removed.
- 5. The partial evaluator may process the execution code of the advice body. It thus instantiates shadows of join points in the advice body. By recursively following the steps from 3, 'advised advice execution' is also compiled.

As is mentioned in the above step 1, we run partial evaluation with respect to each method definition. This is because the applicable method for a method call can not be determined at compile-time in object-oriented languages. Therefore, we start partially evaluation the **execute** function with its method parameter. The rest of the parameters (env and jp) are set to unknown at partial evaluation time. The residual program serves as a compiled (or statically woven) code of the method written in Scheme. The function is stored in a dispatch table so that it will be directly called at run-time.

For partial evaluation, we used PGG, an offline partial evaluator for Scheme[19].

# **3.2 How AJD is Partially Evaluated**

An offline partial evaluator processes a program in the following way. It first annotates subexpressions in the program as either *static* or *dynamic*, based on their dependency on the statically known parameters. Those annotations are often called *binding-times*. It then processes the program from the beginning by actually evaluating static expressions and by returning symbolic expressions for dynamic expressions. The resulted program, which is called *residual program*, consists of a dynamic expressions in which statically computed values are embedded.

This subsection explains how the AJD interpreter is partially evaluated with respect to a subject program, by emphasizing what operations can be performed at partial evaluation time. Although the partial evaluation is an automatic process, we believe understanding this process is crucially important for identifying information available at compiletime and also for developing better insights into design of hand-written compilers.

#### 3.2.1 Compilation of Expressions

The essence of the Futamura projection is to perform computation involving exp at partial evaluation time. Specialization of execute with each static method makes eval of exp static, and subsequent execution keeps this static property of exp. In contrast, call applies the method parameter as a dynamic value to execute due to the nature of dynamic dispatching in object-oriented languages. We therefore configure<sup>4</sup> the partial evaluator not to process execute from call so that it will not 'downgrade' the binding-time of exp to dynamic.

The environment (env) is treated as dynamic. With more careful interpreter design, we could make it *partially-static* data, in which variables are static and values are dynamic. However, this is not the focus of this paper.

#### 3.2.2 Compilation of Advice

As is mentioned in Section 3.1, our compilation framework inserts advice bodies into their applicable shadows of join points with appropriate guards. Below, we explain how this is done by the partial evaluator.

1. A wrapper (e.g., Figure 5) creates a join point upon calling weave. The first three fields of the join point, namely kind, within and name, are static because they merely depend on the program text. The rest fields have values computed at run-time. Those static fields

<sup>4</sup>To do so, we rewrite call to call execute\* instead of execute, and manually give dynamic binding-time to execute\*.

could be passed to the weaver either by using partiallystatic data structure[4] or by rewriting the program to keep those three values in a split data structure. We took the latter approach for the ease of debugging and also for other technical reasons.

- 2. Function weave (Figure 6) is executed with a partially static join point, an action, and dynamic arguments. Since the advice definitions are statically available, the partial evaluator unrolls loops that test each advice definition (*i.e.*, for-each in eval-befores/afters).
- 3. As explained in Section 3.2.3, matching a static pointcut to a partially static join point may result in either a static or dynamic value. Therefore, the test-andexecute sequence (in eval-before/after) become one of the following three:
  - **Statically false:** No action is taken; i.e., no code is inserted into compiled code.
  - **Statically true:** The body of the advice is partially evaluated; *i.e.*, the body is inserted in compiled code without guards.
  - Dynamic: In this case, partial evaluation of pointcut-match? generates an if expression whose then-clause is the above 'statically true' case and the else-clause is 'statically false' case. Essentially, the advice body is inserted with a guard.
- 4. In the statically true or dynamic cases at the above step, the partial evaluator processes the evaluation of the advice body. Since the wrapper of the advice execution calls **weave**, application of advice to the execution of advice body is also compiled.
- 5. When the original action is evaluated (l.4 in Figure 6), the residual code of the original action is inserted. This residual code from **weave** will thus have the original computation surrounded by applicable advice bodies.

#### 3.2.3 Compilation of Pointcut

In step 3 above, pointcut interpreter (Figure 7) is partially evaluated with a static pointcut and a partially static join point. The partial evaluation process depends on the type of the pointcut. For pointcuts that depend on only static fields of a join point (namely call, execution and new), the condition is statically computed to either an environment (as true) or false. For pointcuts that test values in the join point (namely target and args), the partial evaluator returns residual code that dynamically tests the types of the values in the join point. For example, when pointcut-match? is partially evaluated with respect to args(int x), the following expression is returned as residual code.

```
1 (if (types-match? (jp-args jp) '(int))
2 (make-env '(x) (jp-args jp))
3 #f)
```

Logical operators (namely &&, || and !) are partially evaluated into an expression that combines the residual expressions of its sub-pointcuts. The remaining two pointcuts (cflow and cflowbelow) are discussed in the next section.

```
(define point-move
 1
 \mathbf{2}
        (lambda (this1 args2 jp3)
 3
           (let* ((args7 (list (+ (get-field this1 'x)
 \mathbf{4}
                                      (car args2))))
 \mathbf{5}
                   (jp8 (make-jp this1 args7 (jp-state jp3))))
             (if (types-match? args7 '(int))
 \mathbf{6}
 \overline{7}
                  (begin (write "set:")
 8
                          (write (car args7)) (newline)))
9
             (execute* (lookup-method (object-class this1)
10
                                            'set)
                         args7 jp8)))))
11
```

Figure 8: Compiled code of move method of Point class.

The actual pointcut-match? is written in a continuationpassing style so that partially evaluator can reduce a conditional branch in the weaver (ll.15–16 in Figure 6) for the static cases. This is a standard technique in partial evaluation.

#### 3.3 **Compiled Code**

Figure 8 shows the compiled code for the move method defined in Figure 1 combined with the advice given in Figure 3. For readability, we post-processed the residual code by eliminating dead code, propagating constants, renaming variable names, resolving environment accesses, and so forth.<sup>5</sup> Note that the compiled code manipulates only the dynamic portion of join points, as we split them into static and dynamic parts.

It first creates a parameter list (11.3-4) and a join point (1.5)for method call. Lines 6 to 8 are advice body with a guard. The guard checks the residual condition for args pointcut. (Note that no run-time checks are performed for call pointcut.) If matched, the body of the advice is executed(ll.7–8). Finally, the original action (*i.e.*, method call) is performed (ll.9–11).

As we see, advice execution is successfully compiled. Even though there is a shadow of execution join points at the beginning of the method, no advice bodies are inserted in the compiled function as it does not match any advice.

#### **COMPILING CALLING-CONTEXT SEN-**4. SITIVE POINTCUTS

As briefly mentioned before, cflow and cflowbelow pointcuts can investigate join points in the call-stack; i.e., their truth value is sensitive to calling context. Here, we first show a straightforward implementation that is based on a stack of join points. It is inefficient, however, and can not be compiled properly.

We then show a more optimized implementation that can be found in AspectJ compiler. The implementation exploits incremental natures of those pointcuts, and shown as a modified version of AJD. We can also see those pointcuts can be properly compiled by using our compilation framework.

```
after : call(void Point.set(int))
\mathbf{2}
               && cflow(call(void Point.move(int))
3
                         && args(int w)) {
4

#### Figure 9: Advice with cflow Pointcut.

```
(define pointcut-match?
  (lambda (pc jp)
    (cond
          . . .
         ((cflow-pointcut? pc)
          (or (pointcut-match? (pointcut-body pc) jp)
              (pointcut-match? pc (jp-stack jp))))
           )))
```

To keep discussion simple, we only explain cflow in this section. Extending our idea to cflowbelow is easy and actually done in our experimental system.

#### **Calling-Context Sensitive Pointcut: cflow** 4.1

A pointcut cflow(p) matches to any join points if there is a join point that matches to p in its call-stack. Figure 9 is an example. The cflow pointcut in lines 2-3 specifies join points that are created during the method call to move. When this pointcut matches a join point, the args(int w) sub-pointcut gets the parameter to move from the stack.

As a result, execution of the program in Figure 1 with pieces of advice in Figures 3 and 9 prints "set:1" first, "set:6" next, and then "under move:5" followed by "6" last. The call to  $\verb"set"$  from the constructor is not advised by the advice using cflow.

# 4.2 Stack-Based Implementation

A straightforward implementation is to keep a stack of join points and to examine each join point in the stack from the top when cflow is evaluated.

We use the **stack** field in a join point to maintain the stack. Whenever a new join point is created, we record previous join point in the stack field (as is done as the last argument to make-jp in Figure 5). Since join points are passed along method calls, the join points chained by the stack field from the current one form a stack of join points.

The algorithm to evaluate cflow(p) simply runs down the stack until it finds a join point that matches to p, as shown in Figure 10. If it reaches the bottom of the stack, the result is false.

The problem with this implementation is run-time overhead. In order to manage the stack, we have to  $push^6$  a join point each time a new join point is created. Evaluation of cflow takes linear time in the stack depth at worse. When cflow pointcuts in a program match only specific join points, keeping the other join points in the stack and testing them is waste of time and space.

 $<sup>^5\</sup>mathrm{The}$  shown code is compiled with optimized  $\mathtt{cflow}$  evaluation mechanism presented in Section 4.3. Therefore, the last field of the join point is used in a manner different from Figure 5.

 $<sup>^6\</sup>mathrm{By}$  having a pointer to 'current' join point in parameters to each function, pop can be automatically done by returning from the function.

Our compilation does not help those problems. Rather, it highlights the problems. Since relationship between caller and receiver is unknown to the partial evaluator, the stack field of a join point becomes dynamic. Consequently, a stack of join points becomes partially-static in which only some fields of the topmost element are static, while the other elements are totally dynamic. When partial evaluator processes pointcut-match? with a static cflow pointcut and a partially static join point, the second recursive call (l.6 in Figure 10) supplies a dynamic (not partially static) join point. This makes the residual code a loop that dynamically tests each join point in the stack except for the top element<sup>7</sup>; *i.e.*, all the tests involving with cflow are performed at runtime.

# 4.3 State-Based Implementation

A more optimized implementation of cflow in AspectJ compiler is to exploit its incremental nature. This idea can be explained by an example. Assume (as in Figure 9) that there is pointcut "cflow(call(void Point.move(int)))" in a program. The pointcut becomes true once move is called. Then, until the control returns from move (or another call to move is taken place), the truth of the pointcut is unchanged. This means that the system needs only manage the state of each cflow(p) and update that state at the beginning and the end of join points that make p true. Note that the state should be managed by a stack because it may be rewound to its previous state upon returning from actions.

This state-based optimization can be explained in the following regards:

- The state-based implementation avoids repeatedly matching cflow bodies to the same join point in the stack, which can happen in the stack-based implementation. This is achieved by evaluating bodies of cflow at each join point in advance, and records the result as its state for later use.
- The state-based implementation makes static evaluation (*i.e.*, compilation) of **cflow** bodies possible, which can not in the stack-based implementation. This is because bodies are evaluated at each shadow of join points.
- The state-based implementation usually performs a smaller number of stack operations because the state of a cflow pointcut needs not be updated at the join points not matching to its body. On the other hand, the stack-based implementation has to push all join points on the stack.
- The state-based implementation evaluate cflow pointcut in constant time in by having a stack of states for each cflow pointcut.

It is not difficult to implement this idea in AJD. Figure 11 outlines the algorithm. Before running a subject

```
1
     (define weave
       (lambda (jp action args)
\mathbf{2}
3
         (let ((new-jp (update-states *cflow-pointcuts*
4
                                         jp jp)))
5
            ... the body of original weave...
6
           )))
7
     (define update-states
8
      (lambda (pcs jp njp)
9
       (if (null? pcs)
10
         njp
         (update-states (cdr pcs) jp
11
12
            (let ((env (pointcut-match?
13
                         (pointcut-body (car pcs)) jp)))
14
             (if env
15
               (update-state njp (pointcut-id (car pcs))
16
                              env)
17
              njp))))))
18
     (define pointcut-match?
19
       (lambda (pc jp)
20
         (cond ...
21
               ((cflow-pointcut? pc)
22
                (lookup-state jp (pointcut-id pc)))
23
               ...)))
```

Figure 11: State-based Implementation of cflow. (update-state jp id new-state) returns a copy of jp in which id's state is changed to new-state. (lookup-state jp id) returns the state of id in jp.

```
1
     (let* ((val7 ... create a point object ...)
\mathbf{2}
             (args9 '(5))
3
             (jp8 (make-jp this1 args9 (jp-state jp3))))
 \mathbf{4}
        (if (types-match? args9 '(int))
 \mathbf{5}
            (begin
 6
              (execute* (lookup-method (object-class val7)
 7
                            'move)
 8
                          val7 args9
                          (state-update jp8 '_g1
9
10
                                          (new-env '(w) args9)))
11
              ... write and newline ...)
            ... omitted ...))
12
```

Figure 12: Compiled code of "p.move(5)" with cflow advice. (Definitions of variables env6, this1 and jp are omitted.)

program, the system collects all cflow pointcuts in the program, including those appear inside of other cflow pointcuts. The collected pointcuts are stored in a global variable \*cflow-pointcuts\*. The system also gives unique identifiers to them, which are accessible via pointcut-id. We rename the last field of a join point from stack to state, so that it stores the current states of all cflow pointcuts.

When the interpreter creates a join point, it also updates the states of all cflow pointcuts by wrapping weave. The wrapper creates a copy of the new join point with updated cflow states (ll.3-4), and performs the original action. Function update-states evaluates the sub-pointcut of each cflow pointcut (ll.12-13), and updates the state if the result is true (ll.15-16).

Interpretation of cflow pointcut is merely looks up the state in the current join point (1.22).

# 4.4 Compilation Result

Figures 12 and 13 show excerpts of compiled code for the program in Figure 1 with the two pieces of advice in Figures

<sup>&</sup>lt;sup>7</sup>If the partial evaluator supported polyvariant specialization[5]. Otherwise, the test for the topmost element is also coerced to dynamic.

```
1
     (define point-move
 \mathbf{2}
       (lambda (this1 args2 jp3)
 3
        (let* ((args5 (list (+ (get-field this1 'x)
 \mathbf{4}
                                  (car args2))))
 \mathbf{5}
                (jp6 (make-jp this1 args5 (jp-state jp3))))
 \mathbf{6}
         (if (types-match? args5 '(int))
 \overline{7}
           (begin
 8
             (write "set:") (write (car args5)) (newline)
9
             (let* ((val7
10
                       (execute* (lookup-method
                                    (object-class this1) 'set)
11
12
                                  this1 args5 jp6))
13
                      (env8 (state-lookup jp6 '_g1)))
14
                (if env8
                  (begin (write "under move:")
15
                          (write (lookup env8 'w)) (newline)))
16
17
                val7))
18
           ...omitted...))))
```

Figure 13: Compiled code of method move with cflow advice.

3 and 9. The compiler gave \_g1 to the cflow pointcut as its identifier.

Figure 12 corresponds to "p.move(5);" (l.8 in Figure 1). Since the method call to move makes the cflow to true, the compiled code updates the state of \_g1 to an environment created by args pointcut in the join point (ll.9-10), and passes the updated join point to the method.

Figure 13 shows the compiled move method. We can see the additional code for the advice using cflow at lines 13-16. It dynamically evaluates the cflow pointcut by merely looking its state up, and runs the body of advice if the pointcut is true. The value of variable w, which is bound by args pointcut in cflow, is taken from the recorded state of cflow pointcut. Since the state is updated when move is to be called, it gives the argument value to move method.

To summarize, our framework compiles a program with cflow pointcuts into one with state update operations at each join point that matches the sub-pointcut of each cflow pointcut, and state look-ups in the guard of advice bodies. In terms of run-time checks for pointcuts, the code is basically identical to the one generated by AspectJ compiler.

# 5. RELATED WORK

In reflective languages, some crosscutting concerns can be controlled through meta-programming[10, 18]. Several researchers including the first author have successfully compiled reflective programs by using partial evaluation[2, 14, 15]. It is more difficult, however in reflective languages, to ensure successful compilation because the programmer can easily write a meta-program that confuses the partial evaluator.

Wand and the second and the third authors presented a formal model of the procedural version of AJD[20]. Our model is based on this, and used it for compilation and optimizing cflow pointcuts.

Douence et al. showed an operational semantics of an AOP system[8]. Their system is based on a 'monitor' that observes the behavior of subject program, and the weaving

is triggered by means of pattern matching to a stream of events. They also gave a program transformation system that inserts code to trigger the monitor into subject program. Our framework automatically performs this insertion by using partial evaluation.

Andrews proposed process algebras as a formal basis of AOP languages[1]. In his system, advice execution is represented by synchronized processes, and compilation (static weaving) is transformation of processes that removes synchronization. Our experience suggests that powerful transformation techniques like partial evaluator would be needed to effectively remove run-time checks in dynamic join point models.

# 6. CONCLUSION AND FUTURE WORK

In this paper, we presented a compilation framework to an aspect-oriented programming (AOP) language, AJD, based on operational semantics and partial evaluation techniques. The framework explains issues in AOP compilers including identifying shadows of join points, compiling-out pointcuts and recursively applying advice. The optimized cflow implementation in AspectJ compiler can also be explained in this framework.

The use of partial evaluation allows us to keep simple operational semantics in which everything is processed at runtime, and to relate the semantics to compilation. Partial evaluation also allows us to understand the data dependency in our interpreter by means of its binding-time analysis. We believe this approach would be also useful to prototyping new AOP features with effective compilation in mind.

Although our language supports only core features of practical AOP languages, we believe that this work could bridge between formal studies and practical design and implementation of AOP languages.

Future directions of this study could include the following topics. Optimization algorithms could be studied for AOP programs based on our model, for example, elimination of more run-time checks with the aid of static analysis. Our model could be refined into more formal systems so that we could relate between semantics and compilation with correctness proofs. Our system could also be applied to design and test new AOP features.
